ABSTRACT

Purpose: This study assessed the extent to which visual impairment impacts on vision-related quality of life in Indonesia, by comparing four groups of people: those with 1) normal vision, 2) corrected visual impairment, 3) uncorrected visual impairment, and 4) blindness.

Method: Purposive sampling was used. There were 162 respondents, between 21 and 86 years of age. Participants with normal vision and blindness were community-dwellers in Yogyakarta, Indonesia. Those with corrected and uncorrected visual impairment were recruited from an eye clinic. This cross-sectional study used NEI VFQ-25 to assess vision-related quality of life. The total scores and 11 NEI VFQ-25 subscales scores of four respondent groups were analysed using ANOVA, followed by post-hoc analyses to reveal between group differences.

Results: There was a significant difference in the NEI VFQ-25 total scores among the four respondent groups. Respondents with normal vision had the highest score and those with blindness had the lowest. There were also significant differences among the four groups for the 11 subscales. Post-hoc analyses revealed no significant difference between respondents with normal vision and corrected visual impairment in the total and 9 NEI VFQ-25 subscales. Respondents with uncorrected visual impairment and blindness had significantly lower vision-related quality of life compared to those with normal vision or corrected visual impairment in the total and 5 NEI VFQ-25 subscales, indicating that visual impairment decreases vision-related quality of life.

**Conclusion:** Visual impairment has a detrimental impact on a person’s vision-related quality of life. The negative impact of visual impairment can be minimised by correction. Failure to correct visual impairment leads to significantly lower vision-related quality of life.

**Key words:** quality of life, visual acuity, blindness, visual correction, Indonesia

**INTRODUCTION**

The Global Burden of Diseases project, conducted in 2017, reported that blindness and visual impairment caused 1.19% of DALYs globally (Institute for Health Metrics and Evaluation - IHME, 2017). The World Health Organisation’s World Report on Vision, released in 2019, estimated that the number of people with visual impairments worldwide was 2.2 billion (WHO, 2019). The Ministry of Health of the Republic of Indonesia reported that the population with severe visual impairment was more than 2 million people and the number of people with blindness was more than 900,000 (Ministry of Health, 2013).

People with visual impairments experience limitations in carrying out various activities in their lives. They need more time to complete tasks like eating and drinking as they have difficulty in identifying food on a plate or pouring liquid into a glass because of their visual impairment (Pardhan et al, 2015). Independence in conducting activities of daily living decreases as the visual impairment worsens (Christ et al, 2014). Reduced visual acuity, decreased visual field and blurred vision have been associated with lower quality of life (Medeiros et al, 2014; Kim et al, 2017).

Although much is known about the number of people with visual impairment, Indonesia still lacks studies on how visual impairment affects vision-related quality of life. Asrorudin (2014) investigated the effect of eye diseases and visual impairment on vision-related quality of life in a population with severe visual impairment and blindness in Indonesia. However, no studies have compared...
vision-related quality of life between people with normal vision and people with different levels of visual impairment. The comparison between subjects with varying visual function will help elucidate the impact of visual impairment on vision-related quality of life in Indonesia.

**Objective**

Unlike previous studies conducted in Indonesia, this study aimed to compare the quality of life of people with normal vision, corrected visual impairment, uncorrected visual impairment and blindness.

**METHOD**

**Study Sample**

For this cross-sectional study, adults aged 18 years and older were recruited using purposive sampling.

The respondents were classified into 4 groups: Group 1 - people with normal vision, Group 2 - people with corrected visual impairment, Group 3 – people with visual impairment that remained uncorrected although using visual aids, and Group 4 – people who were legally blind. Respondents in Group 2 had either mild or moderate visual impairment, while those in Group 3 had moderate to severe visual impairment.

Those with normal vision and blindness were community dwellers, while participants with visual impairment were recruited from the eye clinic of Bethesda Hospital in Yogyakarta. The respondents with blindness were clients of Badan Sosial Mardi Wuto, a social organisation for people with low vision or blindness.

WHO defines normal vision as visual acuity of 6/6, and blindness as visual acuity worse than 3/60 in the better eye with best correction (WHO, 2019). Visual acuity of respondents with visual impairment was examined by an ophthalmologist, and people with normal vision and blindness were examined by a trained research assistant. People with corrected visual impairment could reach 6/6 visual acuity with visual aids. People with uncorrected visual impairment had visual acuity below 6/6 despite the use of visual aids.
Data Collection
Vision-related quality of life was assessed using National Eye Institute – Vision Function Questionnaire – 25 (NEI VFQ-25). This questionnaire has been used to measure vision-related quality of life among Asian people as well (Suzukamo et al, 2005; Gyawali et al, 2012; Cortina and Hallak, 2015; Saboo et al, 2017; Nickels et al, 2017). NEI VFQ-25 has 12 subscales. The total score is the sum of the 12 subscales scores. The respondents with blindness did not drive, so all of them scored ‘0’ in the driving subscale. Multivariate ANOVA was conducted to test the differences of the NEI-VFQ total and 11 subscale (excluding driving) scores among the four groups with age and sex as covariates. Post-hoc analyses using Dunnett C were conducted to find differences between respondent groups.

Ethics Approval
Ethical clearance was obtained from the Ethics Committee of the Faculty of Medicine, Universitas Kristen Duta Wacana. Detailed explanations were given to the participants to obtain their written informed consent. They were assured that the data would be kept confidential and anonymity would be maintained.

RESULTS
Data was collected from 162 respondents: 41 people with normal vision (Group 1), 41 people with corrected visual impairment (Group 2), 40 people with uncorrected visual impairment (Group 3), and 40 people with blindness (Group 4). There were 28 females and 13 males in Group 1, 25 females and 16 males in Group 2, 19 females and 21 males in Group 3, and 26 females and 14 males in Group 4. The mean and standard deviations of age were: 33.59 ± 7.194 years in Group 1; 52.85 ± 14.307 years in Group 2; 60.98 ± 15.58 years in Group 3; and 46.83 ± 12.09 years in Group 4.

The most common cause of visual impairment in Group 2 was cataract (61%), followed by refractive disorders (24%) and glaucoma (7%). Cataract was also the most common cause of visual impairment in Group 3 (65%), followed by glaucoma (15%), diabetic retinopathy (12.5%) and age-related macular degeneration (2.5%). Meanwhile, among respondents with blindness, measles (87.5%) was the most common cause of blindness since childhood, followed by congenital cataracts (7.5%) and glaucoma and retinal detachment (2.5% each) respectively. The majority of respondents in Group 2 (85%) and Group 3 (65%) had visual impairment for less than 5 years, while respondents in Group 4 had been blind for more than 10 years (100%).
Most respondents had high school education in Group 1 (47.5%) and Group 3 (62.5%). In Group 2, 52.5% had college education, while respondents with blindness had the lowest level of education, as 27.5% had never been to school and 50% had elementary school education.

The majority of respondents in Group 1 and Group 2 were working people (75% and 57.5%, respectively). Half of the study participants in Group 3 worked, and most of those who did not work were pensioners. Almost all of the respondents with blindness (97.5%) worked as masseurs. In Indonesia, the department of social affairs provides free masseur training programmes for people with blindness.

The vision-related quality of life of respondents with normal vision, corrected visual impairment, uncorrected visual impairment and blindness, the results of multivariate ANOVA and post-hoc analyses are presented in Table 1.

### Table 1: Vision-related Quality of Life of People with Normal Vision (Group 1), Corrected Visual Impairment (Group 2), Uncorrected Visual Impairment (Group 3) and Blindness (Group 4), the Results of Multivariate ANOVA and Post-hoc Analyses of the 4 Groups

** p<0.01

*** p<0.001
Multivariate ANOVA that included age and sex as covariates, revealed a significant difference in the NEI VFQ-25 total scores among the four groups of respondents. Group 1 had the highest mean total vision-related quality of life score and Group 4 had the lowest. Post-hoc analyses revealed there was no significant difference between Group 1 and Group 2 respondents, but Group 1 and Group 2 respondents had significantly higher scores than those in Group 3 and Group 4. The total vision-related quality of life score of Group 3 respondents was significantly higher than that of respondents in Group 4.

The mean vision-related quality of life scores of 11 subscales for the four groups of respondents varied, although the mean scores of almost all subscale scores in Group 1 tended to be the highest, and those of Group 4 were likely to be the lowest.

In the general health subscale, post-hoc analysis showed that respondents in Group 1 and Group 2 had significantly higher general health scores than those in Group 3 and Group 4. Respondents in Group 1 and Group 2 were reasonably healthy, as the percentage with self-reported chronic diseases was below 20%. Almost half of the respondents in Group 3 (47.5%) and 35% of those in Group 4 reported having a chronic health condition.

In the general vision subscale, there was no significant difference between Group 1 and Group 2. The correction of Group 2 respondents’ vision had a positive impact on the vision-related quality of life general vision subscale. Respondents in Group 1 and Group 2 had significantly higher scores than respondents of Group 3 and Group 4. Failure to make visual correction, leading to uncorrected visual impairment or even blindness, resulted in lower vision-related quality of life general vision subscale.

The results of near vision activities and distance vision activities subscales showed that visual correction improved people’s ability to conduct near vision activities like reading a book, cooking, sewing or fixing things at home, as well as distance vision activities such as reading street signs, watching movies, and going up and down stairs at night.

In the social functioning subscale, the respondents in Groups 1, 2 and 3 had significantly higher scores than those in Group 4. Despite their visual limitations, Group 2 and Group 3 respondents were able to understand other people’s reactions during conversation or behave as expected when they were visiting people or attending a party. People with blindness had more difficulties in fulfilling their social function which affected their vision-related quality of life.
In the mental health subscale, Group 1 had a significantly higher score than the other three Groups. Group 2 respondents worried about their vision, felt some frustration, had less control over what they did, and worried about being embarrassed due to their visual impairment. Group 3 and Group 4 individuals had bigger problems compared to Group 2 respondents, leading to lower vision-related quality of life.

Post-hoc analysis showed that respondents in Group 1 and Group 2 had significantly higher vision-related quality of life role difficulties subscale than those in Group 3 and Group 4. Respondents in Group 3 and Group 4 thought that they could not complete tasks on time and their performance was lower because of their visual problem. Group 2 individuals did not think that their visual impairment affected their performance.

In the dependency subscale, Group 1 had a significantly higher score than the other Groups. Respondents in Group 2 felt some dependency on what other people said, and needed help from other people because of their visual problems. Individuals in Group 3 and Group 4 had more difficulties than those in Group 2. Group 4 respondents even felt they were forced to stay at home most of the time because of their blindness.

Group 1 and Group 2 individuals had significantly higher peripheral vision subscales than those in Group 3 and Group 4. People in Group 2 did not think that they had significant difficulties in seeing things on the sides, while those in Group 3 and Group 4 did.

There was no significant difference among respondents in Groups 1, 2 and 3 in the colour vision subscale. The three groups had significantly higher scores than those in Group 4. Individuals in Group 2 and Group 3 did not have a significant problem in matching clothes, but those in Group 4 had a lot of problems in performing this task.

**DISCUSSION**

People with normal vision had the highest total NEI VFQ-25 score and those with blindness had the lowest, indicating that vision-related quality of life decreases with the worsening of visual acuity. This is in accordance with other studies conducted in other countries(Fleming et al, 2019; Tharaldsen et al, 2020; Yibekal et al, 2020).
Based on the NEI VFQ-25 subscale analysis, general health was found to be higher in respondents with normal vision and corrected visual impairment than among those with uncorrected visual impairment and blindness. This result suggests that visual acuity may be an indicator of general health. Vision impairment has been associated with chronic conditions in older adults (Court et al, 2014; Crews et al, 2017). People with visual impairment are more likely to have health problems compared to individuals with normal vision. Other researchers found cataract as a predictor of mortality in people aged over 50 years (Zhu et al, 2016; Zhu et al, 2019). A recent review reported poor vision as a risk factor of falls in older adults that may lead to fatality (Joseph et al, 2019).

Subscales of general vision, near vision activities, distance vision activities and peripheral vision showed a significant difference, where respondents with normal vision and corrected visual impairment had higher levels of functioning than individuals with uncorrected visual impairment or blindness. Visual correction may improve vision-related quality of life, while more severe visual impairment may have a more adverse effect on vision-related quality of life. This finding is consistent with other studies showing that best-corrected visual acuity can have positive impact on vision-related quality of life (Råen et al, 2019).

There was no significant difference in the ocular pain subscale among respondents with corrected vision, uncorrected vision and blindness. Ocular pain is commonly associated with ocular surface disease found in most people with glaucoma. The number of respondents with glaucoma in this study was low, and this might explain the result (Baudouin et al, 2013; Tirpack et al, 2019).

This study suggests that visual acuity does not affect social functioning until someone becomes blind. This finding is similar to studies that reported no significant difference in social function between people with normal vision and those with visual impairment (Dev et al, 2014; Heine et al, 2019). Respondents with visual impairment could still carry out their social functions despite obstacles in doing so. Respondents with blindness had many difficulties in carrying out their social functions, and experienced social isolation. Although most of the study participants with blindness worked as masseurs, they waited for clients to visit them because they had problems in moving around the city due to their visual condition.

This study indicates that vision affects mental health. A study on older people has associated self-reported visual impairment with depression (Frank et al,
Vision problems have been associated with worse psychosocial outcomes. Visual impairment causes problems in doing everyday activities, i.e., reading newspapers, recognising people. People with these problems have been reported to have lower life satisfaction, increased depressive symptoms and decreased positive affect (Hajek et al., 2020).

Dependency was different among all four groups; it increased with decreasing visual acuity. This study shows that uncorrected visual impairment can lead to role difficulties, which is consistent with other researchers’ findings that greater visual impairment affects psychosocial parameters, including role difficulty (Zhu et al., 2015). Visual impairment forces the individual to take longer over completing tasks, leading to lower performance.

Despite their corrected vision, respondents in Group 2 had lower quality of life in the dependency subscale than those with normal vision. More than half of the participants in Group 2 wore glasses to correct their visual impairment. Glasses help people perform many activities, but those who wear them complain about the inconvenience of having frequent eye check-ups and getting replacements to keep good vision (Kandel et al., 2017). Without glasses, they need help from others to accomplish tasks. Visual impairment decreases one’s independence in doing activities of daily living, and increases dependence on other people. Individuals with uncorrected visual impairment or blindness have more dependency on others in their daily lives.

This study suggests that neither corrected nor uncorrected visual impairment creates a significant problem in colour vision, but blindness does. This finding is consistent with other researchers who reported a similar result (Zhu et al., 2015).

**Limitations**

This study assessed vision-related quality of life based on the levels of vision, and did not analyse by specific diagnosis.

Comparison between the Groups may have been hampered by the differing sources of research participants. Participants in Groups 1 and 4 were recruited from the community, while participants in Groups 2 and 3 were clients from a hospital eye clinic.
CONCLUSION

It can be concluded that there are significant differences in vision-related quality of life related to people with normal vision, corrected visual impairment, uncorrected visual impairment and blindness. Visual impairment has a detrimental impact on a person’s vision-related quality of life. However, it has differential impacts on different elements of vision-related quality of life. There are no significant differences between people with normal vision and corrected visual impairment in most subscales, suggesting that visual correction can improve vision-related quality of life, and thereby highlighting the importance of visual acuity correction.
